--In currently preferred embodiments, the film shutter 118 is mechanical or electromechanical and the imager shutter 120 is mechanical or electronic. The imager shutter 120 is illustrated by dashed lines to indicate both the position of a mechanical imager shutter 120 and the function of an electronic shutter. When using a CCD, electronic shuttering of the imager 84 can be provided by shifting the accumulated charge under a light shielded provides at a non-photosensitive region. This may be a full frame as in a frame transfer device CCD or a horizontal line in an interline transfer device CCD. Suitable devices and procedures are well known to those of skill in the art. When using a CID, the charge on each pixel is injected into a substrate at the beginning of the exposure. At the end of the exposure, the charge in each pixel is read. The difficulty encountered here is that the first pixel read has less exposure time than the last pixel read. The amount of difference is the time required to read the entire array. This may or may not be significant depending upon the total exposure time and the maximum time needed to read the entire array. CMOS imagers are commonly shuttered by a method called a rolling shutter. CMOS imagers using this method are not preferred, since this shutters each individual line to a common

shutter time, but the exposure time for each line begins sequentially. This means that even with a short exposure time, moving objects will be distorted. Given horizontal motion, vertical features will image diagonally due to the temporal differences in the line-by-line exposure. Another method for shuttering CMOS imagers is described in U.S. Patent No. 5,986,297. In this method, called single frame capture mode, all pixels are allowed to integrate charge during exposure time. At the end of the exposure time, all pixels are simultaneously transferred to the floating diffusion of the device. At this point sequential read out by lines is possible.--
